Get the free chapter from the book Inside Numbers: How to Teach Math in Any Setting: vibration from whole-body vibration machines used for rehabilitation and performance enhancement. Whole-body vibration (WBV) has been shown to induce neurobiological adaptations such as increases in neuron excitability and glial-cell activity, and decrease in cerebral intracortical inhibition. While WBV in functional rehabilitation settings is becoming more common for improving balance, coordination, and muscle strength in adults and/or older adults, its use in the military has been limited by a lack of understanding of the factors that contribute to maximizing the value of WBV. The purpose of this study was to examine the vibration characteristics of popular WBV training machines and determine the safety, feasibility and training characteristics of WBV to support and guide the development of training guidelines for the military and other professional use of WBV. For this study, five machines were selected to simulate a variety of common WBV devices used to train physically active individuals. The selection included machines that typically utilize a seat-based vibration platform, a standing platform, and one that could be used by either individual. Frequency and power-of-vibration (P-of-v) were measured in each machine using a tuning fork and accelerometer. With the exception of the standing platform, the measured parameters were well above the recommended guidelines for maximizing WBV-induced neurobiological adaptations. When consideration was given to the training characteristics of each WBV machine, the standing WBV platform appears to be the least effective for training, with older adults being the primary users of standing WBV. The results of this study suggest that the majority of current WBV machines available to the public or military are likely to not provide adequate WBV to maximize neurobiological adaptations.
